We construct an effective Hamiltonian of interacting bosons, based on scattered radiation off vibrational modes of designed molecular architectures. Making use of the infinite yet countable set of spatial modes representing the scattering of light, we obtain a variable photon-photon interaction in this basis. The effective Hamiltonian Hermiticity is controlled by a geometric factor set by the overlaps of spatial modes. Using this mapping, we relate intensity measurements of the light to correlation functions of the interacting bosons evolving according to the effective Hamiltonian, rendering local as well as nonlocal observables accessible. This architecture may be used to simulate the dynamics of interacting bosons, as well as a designing tool for multiqubit photonic gates in quantum computing applications. Variable hopping, interaction, and confinement of the active space of the bosons are demonstrated on a model system.

DOI: 10.1103/PhysRevLett.123.260502

Quantum machines are fundamentally different from their classical counterparts [1]. Classical computers are implemented using a binary basis set. One of the benefits of this choice is minimal average energy consumption [2], as well as minimal bit error rate in the information transmission of a noisy channel [3]. For such a machine to be useful, it requires large scale integration of fundamental operations, where each level adds to the overall error rate. Deterministic intermediate quantities can be measured and corrected via feedback loops without interrupting the calculation process. In quantum machines, the smallest possible unit of data (qubit) carries a phase that manifests a continuous degree of freedom. Upscaling of operations on qubits is also required for nontrivial tasks. The propagation of quantum information through such integrated system evolves errors continuously as well. This makes the realization of fault tolerant quantum processing challenging and continues to motivate intense scientific effort [4–6]. Quantum simulators based on optical traps pioneered by Cirac, Zoller, and co-workers [7,8] have matured experimentally [9,10]. They are widely used in the study of quantum dynamics, such as spin frustration [10] and thermalization and localization transitions [11,12]. Recently, more applications of lattice gauge theories have been proposed, appealing to simulations of high energy physics [13–15]. While these fascinating quantum simulators offer an unprecedented glimpse into nonequilibrium dynamics, upscaling the number of qubits is just as challenging.

Here we propose a geometric scattering-based spatial photon coupler (SPC) that can be used to simulate quantum dynamics of interacting bosons. The setup is depicted in Fig. 1 and based on “off-resonant scattering” of photons on geometrically arranged distribution of molecules. We show that the scattering process can be mapped into the effective Hamiltonian,

\[ H_{\text{eff}} = \sum_{nk} \Theta_{nk} a_k^\dagger \hat{a}_k - \sum_{nklm} U_{nklm} a_n^\dagger a_k^\dagger a_l a_m, \tag{1} \]

where \( a_k (a_k^\dagger) \) is a discrete bosonic annihilation (creation) operator. The hopping (\( \Theta_{nk} \)) and the interaction (\( U_{nklm} \)) terms are determined by three main quantities: (1) the geometry (design) of the microscopic building blocks, (2) their internal structure (spectrum), and (3) the measurement basis chosen. It holds two significant advantages. First, it can be designed to maintain Hermiticity such that marginal losses in photon number occur [16]; inelastic contributions in this case result in a frequency shift of the incident photon. Second, while the number of connected modes is infinite, it can be confined with intelligent design. Our goal is to shape the induced dynamics constrained by the Hamiltonian in Eq. (1), then read the encoded information from the final photonic wave function.

![Fig. 1. Proposed realization of the geometric SPC. The incident beam is scattered off a molecular architecture, realizing interaction between its spatial components, denoted SB. A single mode as well as any combination of such are addressable, rendering projective measurement in the chosen basis possible. The SBs can be mapped into discrete lattice sites for which cross-correlations can be constructed using the photon statistics.](image-url)
Intensity measurements reveal the scattered bosons (SBs) densities $\hat{n}_s \equiv a_s^\dagger a_s$, evolving on a network (graph) of a topology imposed by $H_{\text{eff}}$ connectivity as depicted in Fig. 1. $\tau$ denotes the interaction time, beyond which $U_{nlm} = 0$.

We consider arbitrary initial superposition of spatial modes, reflecting some initial (multiple-photon) distribution of SBs. One possibility of particular interest to the simulation of interacting bosons is a (normalized) product of $N$ single-photon states $|1\rangle = \sum_n C_n a_n^\dagger 0|0\rangle$, corresponding to initially noninteracting bosons. One way to achieve that is by direct state preparation. Another is via two-mode spontaneous parametric down-converter source in which one photon is scattered while the other serves as the reference for the SB (RSB) as was done in [17] and inspired by [18–22] (see [23]). In both manifestations, the RSBs are used to extract the SB statistics, which is first scattered as depicted in Fig. 1. Surveying the SB statistics using cross-correlations with RSBs, renders “local” $\propto \langle \hat{n}_s(r) \rangle$ and “nonlocal” quantities $\propto \sum_n \langle \hat{n}_s(0) \hat{n}_s(r) \rangle$ accessible. While conventional quantum simulators are limited by the number of physical qubits, the proposed geometric SPC benefits from controlled—potentially infinite—number of participating modes. These characteristics are highly desirable for simulating thermodynamic properties of interacting particles.

**Constructing the effective Hamiltonian.**—Off-resonant light-matter interaction is given by the minimal coupling Hamiltonian,

$$H_{\mu \phi} = \int d\sigma(r, t) A^2(r, t),$$

where $\mu$ and $\phi$ denote the matter and photon fields, respectively. The interaction of radiation modes is mediated by the charge-density operator $\sigma(r)$. The vector potential in the paraxial approximation takes the form $A_{\mu}(r, t) = \sum_{\sigma, l, p} \int_0^\infty dk_0 C(k_0)|A_{\mu l p}(k_0)\rangle e^{ik_0(z-ct)} + \text{H.c.}|,$ where $k_0$ is the wave vector in the longitudinal direction, $C(k_0) = (1 + \sigma^2 / 16\pi^2 |\epsilon_0 k_0|^2)^{1/2}$ and $\theta = q/\sqrt{2}k_0^2$ is the degree of paraxiality [24,25]. The vector potential operator is defined by $A_{\mu l p}(k_0) = e_\mu \hat{a}_{\sigma, \mu, l, p}(k_0)\langle \mu | \psi_{l p}(\rho, z; k_0) | \rangle$, where $h = c = 1$. $\rho$ is the polar distance (cylindrical coordinates) and the indices $l, p$ label the spatial basis set $\psi_{l p}(\rho, z; k_0)$ [24,25], the Laguerre-Gauss (LG) basis is used. Any complete basis that is a solution of the paraxial equation, such as Hermite-Gauss (HG) or Ince-Gauss can be used. Here $e_\sigma = (\alpha - i\alpha\varepsilon)/\sqrt{2}$ is the polarization vector [circular for LG modes (linear for HG)] and $\sigma = \pm 1$. The field (creation and annihilation) operators in the paraxial basis satisfy the canonical commutation relations $[\hat{a}_{\sigma, l, p}(k_0), \hat{a}_{\sigma', l', p'}(k_0')] = \delta_{\sigma, \sigma'} \delta_{l, l'} \delta_{p, p'} \delta(k_0 - k_0')$. The paraxial basis is given by the transformation of the standard operators $\hat{a}_{\sigma, l, p}(k_0) = \int d^2q \phi_{l p}^\dagger(q) \hat{a}_{\sigma}(q)$. This basis has the following properties:

$$\sum_{l, p} \phi_{l p}^\dagger(q) \psi_{l p}(\rho, z, k_0) = e^{i q \rho - k_0 \theta z},$$

$$\int d^2 q \phi_{l p}^\dagger(q) \phi_{l q}(q) = \delta(l, q),$$

where $q$ is the transverse momentum and $\phi_{l p}(q)$ is the LG spatial modes Fourier transform at $z = 0$. The full Hamiltonian is given by $H = H_0 + H_{\mu \phi}$, where $H_0 = H_\phi + H_\mu$ is the noninteracting Hamiltonian of the radiation ($\phi$) and matter ($\mu$). With these notations, the interaction Hamiltonian can be recast in the form

$$H_{\mu \phi} = \sum_{kq} \sigma_{k-q} a_k^\dagger a_q + \sigma_{k-q} a_k a_q^\dagger,$$

where the highly oscillating terms corresponding to $a_k a_q$ and $a_k^\dagger a_q^\dagger$ are neglected. The matter Hamiltonian is given by $H_\mu = \sum_{i,j} c_{i a}^\dagger c_{j a} + \text{H.c.}$, where $c_{i a}^\dagger (c_{i a})$ is the bosonic annihilation (creation) operator with the canonical commutation relations $[c_{i a}, c_{j b}^\dagger] = \delta_{a, b} \delta_{i, j}$. The vibrational modes are labeled $i$ and scatters by $a$. The charge-density operator reads $\sigma_k = \sum_{i=1}^N f_{a}(k)^c_{i a} c_{i a}^\dagger$, where $f_{a}(k) = e^{ikr} w(k)$, $w(k)$ are the localized molecular orbital and $r_a$ scatterer’s positions. We then calculate the effective photon-photon interaction using the Schrieffer-Wolff transformation [see Appendix (B.1) of the Supplemental Material [26] for detailed derivation], follows by a transformation of the momentum representation into superposition the SBs.

**The SB representation.**—Using the above definitions for the Bogoliubov transformation from momentum space to the Schmidt representation $a_k = \sum_n \hat{a}_n(k) a_n$, where $a_n$ is the Schmidt boson annihilation operator and $n$ is a shorthand notation for the two quantum numbers $l, p$ introduced in the expression for the vector potential. The free Hamiltonian reads, assuming a single longitudinal mode at $\omega_0$, $H_\phi = \omega_0 \sum_n \hat{a}_n^\dagger a_n$. The off-diagonal contributions to Eq. (1)—namely, the hopping terms—are given by (see Supplemental Material [26] for detailed derivation),

$$\hat{t}_{\text{coh}} = \sum_{nm} \phi_{nm}^\dagger a_n \hat{a}_m + \text{H.c.},$$

$$\hat{t}_{\text{inc}} = \sum_{nm} \phi_{nm}^\dagger (\Delta_n) \hat{a}_n \hat{a}_m + \phi_{nm}^\dagger (-\Delta_n) \hat{a}_m^\dagger \hat{a}_n,$$

with the hopping coefficients

260502-2
\[ \varphi_{nm}^{coh} = 2 \sum_{\alpha \neq \beta} \sum_{k,q,s} e^{-i(k-q)\epsilon_n + i(s-q)\epsilon_\beta} \times \phi_n^*(k) w_\alpha^*(k-q) w_\beta^*(s-q) \phi_m(s) / q^2 - k^2 \]

(7a)

\[ \varphi_{nm}^{inc}(\Delta_i) = 2 \sum_{\alpha} \sum_{k,q,s} e^{-i(k-s)\epsilon_n} \times \phi_n^*(k) w_\alpha^*(k-q) w_\alpha^*(q-q') \phi_m(s) / q^2 - (k^2 + \Delta_i) \]  

(7b)

and \( \Delta_i = 2\omega_\alpha \epsilon_{\alpha} \). Assuming a slowly varying orbital in momentum domain (point particle limit) significantly simplifies Eqs. (7a) and (7b). When the interparticle distance is much smaller than the transverse wave vector \( r_{\text{eff}} \ll \lambda_\perp \), the coherent hopping [Eq. (7a)] is granted an intuitive form, carrying spatial contributions due to the phase difference of scattered modes. Introducing a cutoff frequency \( \Lambda \) such that \(|r_{\text{eff}}|/\Lambda \leq |r_{\text{eff}}|/k \ll 1 \) and \( q > 1/\Lambda \), we obtain

\[ \varphi_{nm}^{coh} = g_{\text{coh}} \sum_{\alpha \neq \beta} \psi_n^*(\epsilon_n) \psi_m(\epsilon_\beta), \]

(8a)

\[ \varphi_{nk}^{inc} = g_{\text{inc}} \sum_{\alpha} \psi_n^*(\epsilon_n) \psi_k(\epsilon_\alpha). \]

(8b)

Note that these approximations are not essential, yet they grant important intuition; see Appendix B for the exact expressions. The overall SB hopping coefficient is given by \( \Theta_{nk} = \omega_0(\delta_{nk} - \varphi_{nk}^{coh} - \varphi_{nk}^{inc}). \)

The interaction term in Eq. (1) can be displayed in a form that separates the geometrical factor from the basis-dependent one

\[ V_{nmkl} = -\sum_{\ell' s'} S_{\ell' s'} V_{nm\ell' s'} \]

Here \( V_{nlkm} \) is the basis-dependent four-mode “scattering potential”

\[ V_{nlkm} = \sum_i \int d^2k d^2q \phi_n^*(k) \phi_k(k) \times \left( \frac{1}{k^2 - q^2 - \Delta_i} \right) \phi_\ell(q) \phi_\ell^*(q), \]

(9)

and the geometric structural tensor \( S_{\ell' s'} = \sum_\alpha f^*_{\ell' \ell} f_{s' s} \), using concatenation of basis \( \leftrightarrow \) geometry transformation \( f^*_{\ell m} = \psi_n^*(\epsilon_n) \psi_m(\epsilon_\alpha) \), isolating basis-dependent properties from the geometric characteristics. The effective Hamiltonian is finally given by Eq. (1).

**The scattering potential in the Laguerre-Gauss basis.** —

The target effective interaction to be simulated is manipulated and designed using three main ingredients: (i) purely geometric and defined by the arrangement of charges, (ii) the internal structure of each charge (\( \Delta_i \)), and (iii) the choice of basis. While the geometric component appears in the expressions for both the interaction and hopping terms, the charge spectral structure contributes to the scattering potential of Eq. (9) alone. We now study the effects of \( \Delta \) on the interaction that is basis dependent yet geometry independent. The scattering potential \( V_{nlkm} \) involves coupling between four modes. Equation (9) can be further simplified using the LG basis [see Eq. (35B) of the Supplemental Material [26]]. The structure of the scattering potential as a function of \( \Delta \) for a two-level system is depicted in Fig. 2. For all values of \( \Delta \), the relation between the first and last two modes \([n, k \text{ and } l, m \text{ of Eq. } (1)]\) resembles a Kronecker delta. It is given by the partial traces \( V_{nl} = tr_{\text{kl}} V_{nlkl} \approx \delta_{nm} \) and \( V_{kl} = tr_{nm} V_{nlkl} \approx \delta_{kl} \) and depicted in Fig. 2(a). This property simplifies the effective Hamiltonian to

\[ H_{\text{eff}}^{\text{LG}} = \sum_{n,k} \Theta_{nk} a_n^\dagger a_k - \sum_{n,k} U_{nk} n_k \hat{n}_k, \]

(10)

\[ \Delta = 0 \]

\[ \Delta/q_{\text{max}} = 10^{-3} \]

\[ \Delta/q_{\text{max}} = 10^{-2} \]

\[ \Delta/q_{\text{max}} = 2 \times 10^{-2} \]

\[ \Delta/q_{\text{max}} = 5 \times 10^{-2} \]
where $\hat{n}_k = a_k^\dagger a_k$ is the number operator and $U_{nk} = \sum_{lm} U_{nlm} \delta_{nl} \delta_{km}$. The effective potential between the first and last two modes of Eq. (1) spreads to neighboring modes with increasing values of $\Delta/q_{\text{max}}^2$, where $q_{\text{max}}$ is the cutoff wave vector in the numerical calculation. This behavior is summarized in Fig. 2(a) and demonstrated separately for the selected values in Figs. 2(b) and 2(c). At large values of $\Delta/q_{\text{max}}^2$ the scattering occurs between more distant modes, corresponding to energy exchange with the matter. Extension of this result to a system of charges composed of a more complex internal structure is given by a straightforward summation, resulting in longer-range interaction.

**Illustrative example of the effective Hamiltonian.**—We derive the effective Hamiltonian for molecules in cylindrical architecture, in which controlled hopping can confine the dynamics to a restricted subspace. We consider a uniform distribution of molecules filling a hollow cylinder (UC) of inner radius $a$ and outer radius $b$ as shown in Fig. 3. The boundary radius $c$ is defined such that 95% of the power of the incident radial mode for which $n = 25$ is contained within the calculation range of the numerical simulation (the chosen cutoff mode).

In this case, the geometric coefficient of the hopping terms in Eqs. (8a) and (8b) as well as the interaction can be used to confine the dynamics in a controlled subspace. By varying $a$ and $b$, the hopping range depicted in Figs. 4(a) and 4(d) can be controlled. Figure 4 along with Eqs. (8a) and (8b) show that hopping within the set of modes corresponding to the positive geometric factor is energetically favorable. These positive contributions are surrounded by negative ones, which are costly energetically, resulting in effective confinement. In this setup, the single-molecule field scattering presented in Eq. (8b) dominates the hopping dynamics and the coherent hopping term of Eq. (8a) is suppressed. This is verified by the vanishing structure factor in a disordered lattice or, equivalently, from the closure relations of the LG basis combined with orthogonality [Eqs. (4c) and (4b)]. Using Eq. (4a) one can estimate that for $q_{\text{max}} = 10^{-2} k_0$ and $\Delta z = 10^2 \lambda_0$ the modal attenuation factor is $\exp(-2\pi 10^{-2} \rho)$, which yields $\approx 94\%$ of the incoming photon flux at the output for $l = p = 2$. This geometry simulates the dynamics of the Hamiltonian $H_{\text{eff}}^G = H_{\text{UC}},$

\[ H_{\text{UC}} = \sum_{(n,k) \in D_D} \Theta_{nk} a_k^\dagger a_k - \sum_{n,k \in D_D} U_{nk} \hat{n}_n \hat{n}_k, \]

where $(n,k)$ stands for nearest neighbors. $D_D$ is a domain determined by the geometry in which the hopping occurs, as shown in Fig. 4. $D_{\Delta}$ is the domain set by $\Delta$ for which several illustrations are depicted in Fig. 2.

**Discussion.**—We have developed a geometric SPC, shaping photon-photon interactions via geometric design of the coupling between spatial modes, using the setup depicted in Fig. 1. Quantum dynamics of interacting bosons described by the Hamiltonian of Eq. (1) can be simulated and directly measured using the above ingredients.

The dynamics of the SBs constrained by the Eq. (1) is controlled by the following three main quantities: the geometric distribution of molecules, their internal structure, and the choice of spatial basis. The dynamics induced by the geometric SPC depicted in Fig. 3 can be restricted to a finite set of modes as demonstrated in Fig. 4. This offers a “purpose-computing platform” to a class of problems with exponential complexity. There is a growing interest in purpose machines, built for the solution of a specific task, *e.g.*, coherent Ising machines [27,28]. These structures are designed to solve efficiently Ising models on graphs with programmable connectivity. Their usefulness stems from the well-known mapping between the Ising model ground state search problem and combinatorial optimization problems in polynomial time [29] (both nondeterministic

Positive contributions are energetically favorable.](image)
polynomial-time hardness). The proposed setup is also applicable as a quantum (light) state-preparation technique, as well as a multiphoton gate in a photonic quantum processor.

In molecular systems, the number of vibrational modes \( N_{\text{vib}} \) is proportional to the number of atoms \( N_e \) according to \( N_{\text{vib}} = 3N_e - 6 \). The number of electronic states corresponds to the number of electrons \( N_e \). Good candidates would be systems containing few vibrational modes while having a large number of electrons that potentially provide strong coupling of the vibrational modes with an applied electromagnetic field. Short wavelength tabletop x-ray sources that couple off-resonantly between the vibrational modes provide intriguing possibility for source realization [30]. Longer wavelength sources for which sophisticated measurement techniques are more mature may be possible, although the coupling between the modes may take more complicated forms.

[26] See Supplemental Material at http://link.aps.org/supplemental/10.1103/PhysRevLett.123.260502 for the derivation of the effective Hamiltonian including: Hopping terms in Eqs. (6a) and (6b), their coefficients in Eqs. (7a) and (7b) and their approximated form of Eqs. (8a) and (8b) and the general scattering potential in Eq. (9) as well as the LG mode expansion in Eq. (10).

Supplementary materials for “Scattering-based geometric shaping of photon-photon interactions”

Our goal is to construct controlled interaction between these modes that will emulate the one of a desired quantum system. For this, we consider the setup in which initially entangled beam given by a certain Schmidt decomposition interacts with the charge distribution (CD).

Appendix A: Full Hamiltonian of Schmidt bosons

This is a straightforward derivation of the light matter coupling in the Schmidt basis. It is exact and therefore the effective interaction is not clearly pronounced.

The interaction Hamiltonian for a flat CD architecture around some \( z_0 \) is given by,

\[
\mathcal{H}_{\mu \phi} = B_{k_0} \int d\rho \sigma (\rho, t) \times \sum_{l,p} \int_0^\infty dk_0 \left[ A_{lp}^{(+)} (k_0) e^{ik_0(z_0-ct)} + h.c. \right]
\]

\[
\times \sum_{m,n} \int_0^\infty dk'_0 \left[ A_{mn}^{(+)} (k'_0) e^{ik'_0(z_0-ct)} + h.c. \right],
\]

where, \( A_{lp}^{(+)} (k_0) = \hat{a}_{l,p} (k_0) \psi_{l,p} (\rho, z; k_0) \) and \( B_{k_0} = C^2 (k_0) \) at the central frequency. When the Rayleigh range is long enough, we can take \( k_0 \) to be constant throughout the integration over \( k_0 \) and absorb the factor due to \( \int dk_0 e^{ik_0z_0} \) into the overall prefactor \( A \). For brevity we will omit the constants \( z_0 \) and \( k_0 \) from now on. We relabel the indices \((l, p) = k\) and \((m, n) = n\) and define the following projection integrals,

\[
\theta_{nk} (t) = \int d^2 \rho \psi^*_n (\rho) \sigma (\rho, t) \psi_k (\rho),
\]

\[
\kappa_{nk} (t) = \int d^2 \rho \psi_n (\rho) \sigma (\rho, t) \psi_k (\rho).
\]

When \( \sigma (\rho, t) \) is time independent or varies slowly, \( \kappa_{nk} e^{\pm i2\omega_0 t} \) terms that correspond to \( a_n a_k \) and \( a_n^\dagger a_k^\dagger \) are fast oscillating and self average while the cross terms show canceling phase contributions resulting in the Hamiltonian,

\[
\mathcal{H}_{\mu \phi} = A \sum_{n,k} \theta_{nk} a_n^\dagger a_k + \theta_{kn} a_n a_k^\dagger,
\]

furthermore, the field Hamiltonian is further simplified as monochromatic and given in terms of the Schmidt bosons,

\[
\mathcal{H}_{\phi} = \omega_0 \sum_{n,k} t_{nk} a_n^\dagger a_k,
\]

\[
t_{nk} = \int d^2 \rho \psi^*_n (\rho) \psi_k (\rho) = \delta_{nk},
\]

which describes boson hopping on a lattice determined by the choice of basis. When the charge density is uniform \( \theta_{nk} \) only renormalize the Schmidt boson hopping term. This Hamiltonian is an interaction term between the HG or LG modes. The initial state of the light to be an entangled pair given by the Schmidt decomposition,

\[
|\Psi\rangle = \sum_n \sqrt{\lambda_n} |\psi_n\rangle_s |\psi_n^*\rangle_i,
\]

where \( \lambda_n \) are the Schmidt coefficients and \( |\psi_n\rangle \) are the Schmidt modes. By modifying the degree of entanglement, we have control over the number of states that are effectively participating in the computation process. This can
be estimated by the Schmidt number $\kappa^{-1} = \sum_n \lambda_n^2$. One advantage of this setup is the ability to measure each state separately as well as functions of these states by projective measurement techniques available experimentally these days. Measuring each state separately corresponds to “local” observables while functions of them to “nonlocal” observables if we consider the Schmidt modes as bosons hoping on a lattice. Additional merit stems from unrestricted Hilbert space dimension that could be simulated. The Number of states is strictly controlled by the degree of initial entanglement. The quantum calculation/simulator is not restricted to the number of entangled physical qubits, it is performed in the two-photon space which is in principle is infinite. Moreover, while reflection symmetry is persevered in the charge distribution, the system will model the dynamics of a closed quantum system (hermitian Hamiltonian). Anti-symmetric parts mimics open system dynamics (coupling to the environment). We stress that the coupling term between Schmidt bosons can be varied in time as well, this is an interesting feature for studying open and closed quantum systems out of equilibrium.

Appendix B: Effective Hamiltonian

We turn to the derivation of the effective Hamiltonian in which the photon-photon interaction term appears in a more intuitive manner. The Hamiltonian is given by,

$$\mathcal{H} = H_0 + H_{\mu\phi} = H_0 + H_\phi + H_{\mu\phi},$$

where $H_{\phi/\mu}$ represents the field/matter respectively and $H_{\mu\phi}$ is the interaction Hamiltonian. The interaction Hamiltonian can be written in the following form,

$$H_{\mu\phi} = \int dr \sigma(r) A^2(r) \approx \sum_{kq} \sigma_k^{\dagger} a_{k-q}^{\dagger} a_q + \sigma_{k-q} a_k a_q,$$

where the terms that are proportional to $a_k a_q, (a_k a_q)^\dagger$ where neglected. We model the charge density operator as,

$$\sigma(r) = \sum_{\alpha,i,j} w(r - r_\alpha) c_{i,\alpha}^\dagger c_{j,\alpha},$$

$$\sigma_k = \sum_{\alpha=1}^N f_\alpha(k) c_{i,\alpha}^\dagger c_{j,\alpha},$$

such that $f_\alpha(k) = e^{i k \cdot r_\alpha} w(k)$ and $w$ are the localized molecular orbital functions.

1. Schrieffer-Wolff transformation

In order to derive an effective interaction term between the photons we turn to the Schrieffer-Wolff transformation given by the rotation,

$$H' = e^S H e^{-S}.$$

Using the Baker-Campbell-Hausdorff formula we approximate the rotated Hamiltonian to,

$$H_{\text{eff}} = H + [S, H_0] + \frac{1}{2} [S, [S, H_0]] + \ldots$$

It is possible to use this expansion in order to derive the rotated Hamiltonian pertubatively. With the interesting choice $[S, H_0] = -H_{\mu\phi}$ we arrive to second order in the expansion the rotated Hamiltonian,
\[ H_{\text{eff}} = H_0 + \frac{1}{2} [S, H_{\mu\phi}] + O(H^3_{\mu\phi}) \]

We start by computing the following commutation relations,

\[ \eta = [H_0, H_{\mu\phi}] \]
\[ \eta_\phi + \eta_\mu = [H_\phi, H_{\mu\phi}] + [H_\mu, H_{\mu\phi}] , \]

with the matter Hamiltonian \( H_\mu = \sum_{\alpha,i} \epsilon_{i,\alpha} c^\dagger_{i,\alpha} c_{i,\alpha} \) counting bosonic excitations. For \( [c_{i,\alpha}, c^\dagger_{j,\beta}] = \delta_{\alpha\beta} \delta_{i,j} \) and \( (\hbar = 1) \) we obtain,

\[ \eta_\phi = \sum_{kq} (\omega_k - \omega_q) \sigma_{k-q}^+ a_k a_q + (\omega_q - \omega_k) \sigma_{k-q}^+ a_k a_q, \]
\[ \eta_\mu = \sum_{\alpha,i,j,k,q} (\epsilon_{i,\alpha} - \epsilon_{j,\alpha}) \left[ f_{\alpha}^* (k-q) a_k^+ a_q + f_{\alpha} (k-q) a_k a_q^+ \right] \epsilon_{i,\alpha} c_{j,\alpha}, \]

this allows us to derive the generator,

\[ S = \sum_{\alpha,i,j,k,q} \left[ A_{\alpha ij}^k a_k^+ a_q + B_{\alpha ij}^k a_k a_q^+ \right] \epsilon_{i,\alpha} c_{j,\alpha}, \]

with the coupling tensors,

\[ A_{\alpha ij}^k = \frac{f_{\alpha}^* (k-q)}{\epsilon_{ij} + \Delta_{kq}}, \]
\[ B_{\alpha ij}^k = \frac{f_{\alpha} (k-q)}{\epsilon_{ij} - \Delta_{kq}}, \]

where \( \Delta_{kq} = \omega_k - \omega_q \) and \( \epsilon_i - \epsilon_j = \epsilon_{ij} \). The effective Hamiltonian after tracing over the matter is given by,

\[ H_{\text{eff}} = H_\phi + \]
\[ + 2 \sum_{\alpha,\beta,k,q,s} \frac{f_{\alpha}^* (k-q) f_{\beta} (s-q)}{\Delta_{kq}} a_k^+ a_s + \text{h.c.} \]  
\[ + 2 \sum_{k,q,s} \left[ f_{\alpha} (s-q) + f_{\alpha}^* (s-q) \right] \left[ \frac{f_{\alpha}^* (k-q)}{\Delta_{kq} + \epsilon_{ij}} a_k^+ a_s + \frac{f_{\alpha} (k-q)}{\Delta_{kq} - \epsilon_{ij}} a_k a_s^+ \right] \]  
\[ + 8 \sum_{\alpha,i,j,k,q,s,r} \frac{\epsilon_{ij}}{\Delta_{kq} - \epsilon_{ij}} a_k^+ a_q a_s^+ a_k. \]

2. Derivation of the effective Schmidt-boson hamiltonian

The first term correspond to coherent, two-body mediated transport of momentum between radiation modes, the second term to incoherent, single-body transport of field momentum and the last correspond to photon-photon single-body-mediated interaction. We refer to hopping due to interaction with multiple (single) coherent (incoherent) hopping.

\[ t_{coh} = -\omega_0 \sum_{\alpha \neq \beta} \sum_{k, q} e^{-i k \cdot r_\alpha + i q \cdot r_\beta} g_{kq}(r_\alpha, r_\beta) a_k^\dagger a_q + h.c., \]  

(B2)

where,

\[ g_{kq}(r_\alpha, r_\beta) = 2 \int d^2q \frac{w^*_\alpha (k - q') w_\beta (q - q')}{q'^2 - k^2} e^{-i q' \cdot (r_\beta - r_\alpha)}, \]  

(B3)

In the point particle approximation we obtain,

\[ g_{kq}(r_\alpha, r_\beta) \approx 2 \int q' \, dq' \frac{\int_0(q' r_{\beta \alpha})}{q'^2 - k^2}. \]  

(B4)

In the next section we will integrate over the continuous wavevector and end up with discrete Schmidt boson operators. \( g_{kq}^{coh} \) is carefully regularized with the cutoff \( \Lambda \), \( g_{kq}^{coh} = 2 \int_\Lambda dq \frac{\sin(q)}{q^2 - (r_{\beta \alpha} k)^2} \). When \( r_{\beta \alpha} k / \Lambda < r_{\beta \alpha} k \ll 1 \) and \( q > 1 / \Lambda \) it is instructive to imagine a setup in which \( |r_{\alpha \beta}| \ll \lambda \) such that the \( J_0 \approx 1 \) is flat and the renormalized coherent hopping carry the spatial contribution due to the phase-difference resulting in,

\[ g_{kq}(r_\alpha, r_\beta) \approx g_{kq}^{coh}, \]  

(B5)

and the point charge approximation results in,

\[ t_{coh} = -\omega_0 g_{kq}^{coh} \sum_{k, q} S_{kq} a_k^\dagger a_q + h.c., \]  

(B6)

where \( S_{kq} = \sum_{\alpha \neq \beta} e^{-i k \cdot r_\alpha + i q \cdot r_\beta} \) is the geometric structure factor that vanishes for disordered geometries and dominates when there is long range order.

\[ g_{kq}^{inc}(\Delta_i) = 2 \int d^2q \frac{w^*_\alpha (k - q) w_\alpha (s - q)}{q^2 - (k^2 + \Delta_i)}, \]  

(B8)

and the radial component can be carried via analytical continuation to the complex plane. When the momentum distribution of the molecular orbital functions is uniform in the integration region (point particle limit), \( \sum_i g_{kq}^{inc}(\Delta_i) = g_{inc} \) in a similar procedure to the coherent hopping. The incoherent hopping term is finally given by,

\[ t_{inc} = -\omega_0 g_{inc} \sum_{\alpha, k, q} e^{-i (k - q) \cdot r_\alpha} a_k^\dagger a_q + h.c. \]  

(B9)
3. Schmidt-Boson representation

Using the above definitions for the Bogoliubov transformation from momentum space to the Schmidt representation,

\[ a_k = \sum_n \phi_n (k) a_n, \]  

(B10)

where \( a_n \) is the Schmidt boson annihilation operator. The free Hamiltonian reads,

\[ H_\phi = \sum_k \omega_k a_k^\dagger a_k, \]  

(B11)

assuming a single longitudinal mode \( \omega_0 \) we get,

\[ H_\phi = \omega_0 \sum_n a_n^\dagger a_n. \]  

(B12)

\[ \text{a. Hopping} \]

The modal-hopping reads,

\[ t_{coh} = -\omega_0 \sum_{nm} \theta_{nm}^coh a_n^\dagger a_m + h.c., \]  

(B13)

\[ \theta_{nm}^coh = \sum_{\alpha \neq \beta} e^{-i k \cdot r_\alpha + i q \cdot r_\beta} g_{kq} (r_\alpha, r_\beta) \phi_n^* (k) \phi_m (q), \]  

(B14)

where \( \psi_n \) is the real-space representation of \( \phi_n \). This simplifies further in the point-particle limit,

\[ \theta_{nm}^coh = g_{nm}^coh \sum_{\alpha \neq \beta} \psi_n^* (r_\alpha) \psi_m (r_\beta). \]  

(B15)

The incoherent hopping similarly reads,

\[ t_{inc} = -\omega_0 \sum_{nk} \theta_{nk}^inc a_n^\dagger a_k + h.c., \]  

(B16)

\[ \theta_{nk}^inc = g_{nk}^inc \sum_{\alpha} \psi_n^* (r_\alpha) \psi_m (r_\alpha), \]  

(B17)

The over-all Schmidt-boson transport coefficient is given by,

\[ t_{nk} = \omega_0 \left( \delta_{nk} - \theta_{nk}^coh - \theta_{nk}^inc \right), \]

and the Hamiltonian is,

\[ H_{eff} = \sum_{nk} t_{nk} a_n^\dagger a_k + h.c. + H_{\phi-\phi}. \]
We define the terms,
\[ V_{nm}^{1,\alpha}(\epsilon_{ig}) = \int d^2 k d^2 q e^{-i (k-q) \cdot r_\alpha} \phi_n^* (k) \phi_m (q) \frac{q^2 - k^2 + \Delta_i}{q^2 - k^2 + \Delta_i}, \]  
(B18)
\[ f_{nm}^\alpha = \psi_n^* (r_\alpha) \psi_m (r_\alpha), \]  
(B19)
and rewrite the interaction term as,
\[ U_{nmis} = -4 \sum_{\alpha} \int d^2 k d^2 q d^2 k' d^2 q' e^{-i (k-q) \cdot r_\alpha} e^{-i (k'-q') \cdot r_\alpha} \]  
\[ \times \left[ \frac{1}{k^2 - q^2 - \epsilon_{ig}} - \frac{1}{k^2 - q^2 + \epsilon_{ig}} \right] \phi_n^* (k) \phi_m (q) \phi_i^* (k') \phi_s (q') \]  
(B20)
and recall the identity,
\[ e^{ik \cdot r_\alpha} = \sum_n \phi_n^* (k) \psi_n (r_\alpha), \]  
(B21)
then sum the prime coordinates and rewrite the exponents as sums of the spatial modes,
\[ -4 \int d^2 k d^2 q \left[ \frac{1}{k^2 - q^2 - \epsilon_{ig}} - \frac{1}{k^2 - q^2 + \epsilon_{ig}} \right] \phi_n^* (k) \phi_m (q) \sum_{\alpha} e^{-i (k-q) \cdot r_\alpha} \psi_i^* (r_\alpha) \psi_s (r_\alpha) \]  
rewriting the exponent using Eq. B21 the interaction is given by,
\[ \sum_{\alpha} e^{-i (k-q) \cdot r_\alpha} \psi_i^* (r_\alpha) \psi_s (r_\alpha) = \sum_{\alpha} \left[ \sum f_{li}^{\alpha*} f_{is}^{\alpha} \psi_i (r_\alpha) \psi_l (r_\alpha) \right]^* \left[ \sum f_{li}^{\alpha*} f_{is}^{\alpha} \psi_i (r_\alpha) \psi_l (r_\alpha) \right] \]  
\[ = \sum f_{li}^{\alpha*} f_{is}^{\alpha} \sum_{\alpha} f_{li}^{\alpha*} f_{is}^{\alpha}, \]  
(B22)
recasting the interaction term,
\[ U_{nmis} = -4 \sum_{\alpha,i} \int d^2 k d^2 q \]  
\[ \times \phi_n^* (k) \phi_l (k) \left[ \frac{1}{k^2 - q^2 - \Delta_i} - \frac{1}{k^2 - q^2 + \Delta_i} \right] \phi_m (q) \phi_s^* (q), \]  
(B23)
This is the exact (basis dependent) effective interaction term. The four modes scattering on this potential is a property of the chosen basis. The structure factors \( f_{nm}^\alpha \) hold the geometric dependency of the effective interaction which can be designed. It is convenient to define the scattering potential,
\[ V_{nkim} = \int d^2 k d^2 q \]  
\[ \times \phi_n^* (k) \phi_k (k) \left[ \frac{1}{k^2 - q^2 - \Delta_i} - \frac{1}{k^2 - q^2 + \Delta_i} \right] \phi_l (q) \phi_m (q), \]  
(B24)
and the geometric structure factor,
\[ S_{ll's's'} = \sum_{\alpha,i} f_{ll'}^{\alpha*} f_{ss'}^{\alpha}, \]  
(B25)
isolating basis dependent properties from the geometrical characteristics,

$$U_{nmts} = -\sum_{l's'} S_{ll's'} V_{nml's'} ,$$  \hspace{1cm} (B26)

allowing one to study them separately. The effective Hamiltonian is finally given by,

$$H_{eff} = \sum_{n,k} t_{nk} a_n^k a_k - \sum_{nklm} U_{nklm} a_n^k a_k a_m^l a_m.$$  \hspace{1cm} (B27)

4. LG basis

We now recall that each SB has two quantum numbers. For LG modes we can carry the integration over the azimuthal dimension such that $n\to n_r, n_o$ for the radial and azimuthal DOF,

$$-4\sum_{l's'} \int kdkdq \left[ \frac{1}{k^2 - q^2 - \Delta} - \frac{1}{k^2 - q^2 + \Delta} \right] \phi_{n_r}^* (k) \phi_{l_r} (k) \phi_{m_r} (q) \phi_{l'_r} (q)$$

$$\times \delta_{n_o,l'_o} \delta_{m_o,s'_o} \sum_{\alpha} f_{ll's'}^{\alpha*} f_{ss'} \left[ e^{-i\pi (n_r-l'_r)} e^{i\pi (m_r-s'_r)} \right]$$

by exchanging $k \leftrightarrow q$ for the second term in the brackets (negative contribution) absorbing the minus sign we get,

$$-4\sum_{l's'} \int kdkdq \left[ \frac{1}{k^2 - q^2 - \Delta} \right] \left[ \phi_{n_r}^* (k) \phi_{l_r} (k) \phi_{m_r} (q) \phi_{l'_r} (q) + \phi_{n_r}^* (q) \phi_{l_r} (q) \phi_{m_r} (k) \phi_{l'_r} (k) \right]$$

$$\times \delta_{n_o,l'_o} \delta_{m_o,s'_o} \sum_{\alpha} f_{ll's'}^{\alpha*} f_{ss'} \left[ e^{-i\pi (n_r-l'_r)} e^{i\pi (m_r-s'_r)} \right].$$

We can simplify this expression further using an analytical continuation of $k$ and write,

$$\frac{1}{k^2 - q^2 - \Delta} = \lim_{\delta \to 0} \frac{1/k + \sqrt{q^2 + \Delta}}{k - \sqrt{q^2 + \Delta} - i\delta},$$

and perform the integration over $k$ resulting in using the Sokhotski–Plemelj theorem,

$$U_{nmts} = -2\pi \sum_{l's'} \int qdq \left[ \phi_{n_r}^* \left( \sqrt{q^2 + \Delta} \right) \phi_{l_r} \left( \sqrt{q^2 + \Delta} \right) \phi_{m_r} (q) \phi_{l'_r} (q) + \phi_{n_r}^* (q) \phi_{l_r} (q) \phi_{m_r} \left( \sqrt{q^2 + \Delta} \right) \phi_{l'_r} \left( \sqrt{q^2 + \Delta} \right) \right]$$

$$\times \delta_{n_o,l'_o} \delta_{m_o,s'_o} \sum_{\alpha} f_{ll's'}^{\alpha*} f_{ss'} \left[ e^{-i\pi (n_r-l'_r)} e^{i\pi (m_r-s'_r)} \right].$$

When $\Delta$ is large this vanishes, only $q^2 > \Delta$ contribute to the effective interaction. From the general form of the Fourier transform of the LG modes at $z = 0$ we can see exponential suppression of these modes when they are translated,

$$\phi_{lp} (q, \varphi) = \sqrt{\frac{p!}{2\pi (|l| + p)!}} \frac{q^{|l|}}{\sqrt{2}} L_p^{|l|} \left( \frac{q^2}{2} \right) e^{-\frac{q^2}{2}} e^{i\varphi} e^{-i\pi (2p + |l|)},$$

where the last phase factor is responsible for the sign changing term that appeared after the azimuthal integration, and we have beam waist $w_0 = 1$.
