Coupled Electronic and Nuclear Motions during Azobenzene Photoisomerization Monitored by Ultrafast Electron Diffraction

Jérémy R. Rouxel,* Daniel Keefer,* Flavia Aleotti, Artur Nenov, Marco Garavelli, and Shaul Mukamel*

1. INTRODUCTION

Ultrafast electron diffraction (UED) is a well established technique that can resolve molecular structures with femtosecond and angstrom resolutions. We demonstrate theoretically how it can be used to monitor conical intersection dynamics in molecules. Specific contributions to the signal are identified which vanish in the absence of vibronic coherence and offer a direct window into conical intersection paths. A special focus is on hybrid scattering from nuclei and electrons, a process that is unique to electron (rather than X-ray) diffraction and monitors the strongly coupled nuclear and electronic motions in the vicinity of conical intersections. An application is made to the cis to trans isomerization of azobenzene, computed with exact quantum dynamics wavepacket propagation in a reactive two-dimensional nuclear space.

Most UED studies have so far focused on resolving the evolving structure of electronically excited molecules undergoing photophysical and photochemical processes. These have led to striking observations of electronic and nuclear relaxation. However, time-resolved homodyne-detected diffraction signals are not solely determined by the time dependent charge density but should be dissected into various contributions, each having a distinct physical significance. The UED pattern originates from both the electronic \( \sigma_e \) and the nuclear \( \sigma_n \) molecular charge densities. The UED signal from a single molecule is given by a two-point correlation function of the total (electronic + nuclear) charge density. As such, it contains purely electronic, purely nuclear, and hybrid electronic and nuclear contributions. The purely electronic terms are the same as in XRD, up to a prefactor, and this component of the UED signals thus carries the same information as XRD. When this contribution is further expanded in molecular eigenstates, it is possible to single out terms sensitive to molecular coherences. The nuclear and hybrid terms, which do not appear in XRD, offer novel insights into the molecular dynamics and are highly sensitive to conical intersections (CoIns).

Azobenzene has two stable trans and cis isomers in the electronic ground state, see Figure 1. Its photoisomerization has drawn considerable interest for photoswitching applications in materials, neurons and protein folding. Selective optical switching between the two isomers with high quantum yield is possible by using different wavelengths. The isomerization is triggered by photoexcitation from the \( S_0 \) to the \( n\pi^* \) \( S_1 \) state. High-level CASPT2 potential energy surfaces in the reduced space of three nuclear degrees of freedom describing the isomerization reaction were reported in ref 23. The first nuclear coordinate is the carbon–nitrogen–carbon (CNNC) dihedral angle connecting the cis minimum at \( 5^\circ \) with the trans minimum at \( 180^\circ \). The second and third coordinates are the two respective CNN bending

Received: August 6, 2021
angles between the two nitrogen atoms and one adjacent carbon atom, respectively. To simulate nuclear wavepacket dynamics for the cis to trans isomerization, it is sufficient to include one of the two CNN angles, while the other one remains fixed at 116°.13 Symmetry breaking between both angles is necessary to reach the minimum energy conical intersection, that spans a strong nonadiabatic coupling seam between CNN = 127° and 152°. Hybrid pathways have been discussed and known as rotation-assisted inversion or inversion-assisted rotation. The isomerization dynamics time scale exhibits a multiexponential decay with time scales ranging from ≈0.2 ps to ≈12 ps24 for the dynamics in the S1 state. In Figure 2, the nuclear wavepacket amplitude squared is displayed as a function of the torsion and bending angles for different time delays (0, 100, and 200 fs). The average molecular geometry is displayed for each of these three times.

In section 2, we first summarize how the UED signal can be dissected into multiple interaction pathways. Next, we present how the various contributions to the signal, that is, elastic/inelastic and electronic/nuclear contributions, offer different windows into the ultrafast isomerization dynamics. In section 3, we discuss how these contributions can be discriminated experimentally.

Figure 2. Amplitude squared of the excited state wavepacket at $T = 0$, 100, and 200 fs in panels a, b, and c, respectively. Panels d, e, and f show the corresponding averaged molecular geometries at the same time delays.
2. RESULTS

The UED Signals. The UED signal defined in the Materials and Methods section is given by

$$S_{UED}(q, T) = \frac{2}{\epsilon_0 \hbar^2} \frac{1}{q^2} \Re \int dt \, dt' \langle \sigma_T(-q, t) \sigma_T(q, t') \rangle$$

$$\times F_i(t) F^*_i(t') e^{i \omega t (t - t')}$$

$$(1)$$

where $q = k_i - k_r$ is the momentum transfer between the scattered and incoming electron beams with wavevectors $k_i$ and $k_r$, respectively. $\sigma_T = e_{e} + e_N$ is the total charge density given by the sum of the unscreened electronic $e_e$ and nuclear $e_N$ charge densities. $F_i$ is the electron beam temporal envelope. Equation 1 can be further simplified by assuming that (1) no field is initially present in the detector direction (homodyne detection), (2) the signal originates from a single molecule, (3) the electron pulse is impulsive $F_i(t) \propto \delta(t - T)$. Under these conditions, $eq$ 1 becomes

$$S_{UED}(q, T) \propto \frac{1}{q^2} \langle \Psi(T) \sigma_T(-q) \sigma_T(q) | \Psi(T) \rangle$$

$$(2)$$

The electrons + nuclei wave function $| \Psi(T) \rangle = \sum |y_i(T)\rangle |\varphi_i\rangle$ is expanded in the adiabatic basis consisting of products of nuclear $|y_i(T)\rangle$ and electronic $|\varphi_i\rangle$ many-body states in state $i$. $T$ is the delay between the initial actinic pulse launching the dynamics and the electron beam scattering event.

These expressions have close similarities with the tr-XRD signal, but with some notable differences: XRDX only takes the electronic charge density while UED depends on the total electronic + nuclear charge density. In addition, the $1/q^2$ prefactor damps the high $q$ contributions. By expanding the two-point correlation function in $eq$ 2 in the valence electronic states, the 12 contributions to the UED signal can be expressed by the loop diagrams, given in Figure 8 in the Materials and Methods section.

$$S_{UED}(q, T) \propto \sum_{i=1}^{12} S_{Di}(q, T)$$

$$(3)$$

Application to the cis–trans isomerization of Azobenzene. All 12 contributions to the UED signal were calculated for oriented azobenzene molecules. The fixed laboratory frame is displayed in panels d, e, and f of Figure 2. The potential energy surfaces (PES) of the $S_0$ and the $S_1$ states, located in the $S_1$ state is represented by a Gaussian wavepacket centered at the cis geometry. It reaches the CoIns after 70 fs at the geometry displayed in Figure 1. This assumes an excitation of 100% of the ground state into the $S_1$ state. Experimental excitations are usually lower to keep the process in the linear regime and avoid multiphoton processes. A lower than 100% excitation adds a constant background from elastic ground state scattering to the signal. This only affects the relative strengths of the different signatures, but not the qualitative features. Scattering experiments and analysis with low excitation ratios (around 5%) have been demonstrated.

Figure 5 displays the electronic, nuclear, and hybrid contributions to the UED signal in $q-T$ space along the $q_x$, $q_y$, or $q_z$. The top row shows the total signal. The electronic contribution, diagrams (i) to (vi) in Figure 8, displayed in the second row, is the main contribution to the total signal and has already been studied previously for tr-XRD. A careful inspection shows some minor differences between the total signal and the electronic contribution, especially at short time and large $q$ values where the nuclear contributions are visible. This signal displays a particular sensitivity to the CoIn. Along $q_y$, for example, the signal at $q_y = 5$ Å$^{-1}$ starts fading at $T = 70$ fs when the CoIn is being crossed, while another feature appears at $q_y = 8$ Å$^{-1}$. The second row shows the nuclear contributions to the signal, given by diagrams (vii) and (viii) in Figure 8. Initially, the nuclear wavepacket is well localized at the cis geometry and the atomic nuclear charges are centered around their atomic sites. This is why the nuclear signal is more delocalized in $q$ space than its electronic counterpart at the beginning of the dynamics. As the nuclear wavepacket spreads, the electronic density at the atomic sites becomes more delocalized and the signals are dominated by the lower $q$ values as shown in Figure 5. The nuclear contribution contains features at multiple $q$ values that vanish when the CoIn is reached. The final hybrid electronic/nuclear terms are displayed at the bottom row of Figure 5. These are mostly located around low $q$ values where both the electronic and nuclear charge densities overlap in $q$ space. Along $q_y$, the signal contains a clear feature at $10$ Å$^{-1}$ that appears at the onset of the CoIn at 70 fs and vanishes at 170 fs with the vanishing of the coherence between the $S_0$ and the $S_1$ state (Figure 3b). While the electronic contributions in the top row are observable with X-ray diffraction as well, the nuclear and hybrid terms in the middle and bottom rows are unique to UED.
A different partitioning of the 12 contributions to the signal is presented in Figure 6. The top row depicts the elastic contributions (diagrams (i), (ii), (vii), (viii), (ix), and (x), see Figure 8) whereas the bottom row displays the inelastic contributions to the signal ((iii), (iv), (v), (vi), (xi), and (xii)). The inelastic signal reveals the most direct information on the CoIn since it is induced by the coherence created as the CoIn is being crossed.

3. DISCUSSION

Each diagram contributing to the UED signals carries a distinct information regarding the molecular dynamics. The electronic (second row, Figure 5) and nuclear (third row, Figure 5) contributions to the signal measure Fourier transforms of the two-point correlation functions of the electronic and nuclear charge densities, respectively. Additionally, the hybrid electronic/nuclear terms (bottom row, Figure 5) possess unique features of the CoIns region. The hybrid contributions to UED in the \( q \)-values above 5 Å\(^{-1} \), zoomed in Figure 7 bottom panel, are very sensitive to the passage through the CoIn as can be compared with the dynamics of the coherence showed in Figure 7 top panel. The ability to extract them from the total signal would be an invaluable tool to study the dynamics. At conical intersections, the electrons and nuclei move on a comparable time scale and thus become strongly coupled. The hybrid nuclear/electronic term, that is unique to UED, is the most adequate one to observe this coupled motion.

The elastic terms contain products of diagonal matrix elements of the charge density operator that scale as the square of the number of electrons \( N^2 \) in the molecule. On the other hand, the inelastic terms have the scaling of a single valence electron and are therefore much weaker. Nonetheless, they can be separated by energy resolved detection since the scattered electron is shifted in energy by few electron-volts. Finally, by subtracting the different contributions to the frequency-resolved signal from the one without frequency resolution, one can recover the hybrid terms.

Since the electronic charge density is more delocalized than the nuclear one, its contribution to the diffraction pattern is limited to smaller momentum transfer values. At high \( q \) the signal is thus dominated by the nuclear terms. Separating the contributions at smaller \( q \), up to few Å\(^{-1} \) is a more delicate task which will require the use of information derived from other measurements.\(^{28} \) The XRD diffraction pattern is produced by the electronic charge density. Similarly, neutron diffraction patterns solely originate from the nuclear charge density. By proper scaling, for example, following the Mott-Bethe formula for XRD,\(^{29} \) one can subtract these contributions from the UED signal to single out the hybrid electronic/nuclear terms. The UED signal can be alternatively analyzed in combination with time-resolved photoelectron spectroscopy (TRPES) to extract additional energy information.\(^{30} \)

4. CONCLUSIONS

In this work, we have addressed the dissection of UED signals to extract the complete information on the electron and nuclear charge densities.
nuclear molecular dynamics. A perturbative loop diagrams description reveals the existence of hybrid electronic/nuclear terms in the signal. Although these terms are weaker than their purely electronic or nuclear counterparts, they display a high sensitivity to the nuclear dynamics, especially at conical intersections. Experimental efforts targeted at extracting these hybrid contributions should be valuable to gain detailed insight into nonadiabatic dynamics.

To highlight the features of the proposed signal, we have considered an idealized configuration in which the molecule was perfectly oriented. Also, the dynamics in the present study starts with a nuclear wavepacket fully in the excited state. A more realistic approach would assume an extra pump pulse and a partial population of the excited state. Future work should consider the case of a complete or partial rotational averaging and include explicitly the pump pulse in the propagation.

Finally, we demonstrated that UED is sensitive to both electronic and nuclear dynamics, not only to structural changes. This point was also made recently by de Kock et al.\textsuperscript{31}

5. MATERIALS AND METHODS

Signal Definitions. The molecule-beam interaction Hamiltonian for ultrafast ED is

$$H_{\text{int}}^{\text{UED}} = \int dr \, dr' \frac{\sigma_T(r) \sigma_B(r')}{4\pi \epsilon_0 |r - r'|}$$  \hspace{1cm} (4)$$

where $\sigma_T(r) = \sigma_E(r) + \sigma_N(r)$ is the total molecular charge density operator (electron + nuclei) and $\sigma_B(r')$ is the one of the incoming electron beam.
The UED signal is defined by the integrated rate of change of the electron number $\langle N_k \rangle$ in the detector direction:

$$S_{\text{UED}}(k) = \int dt \langle N_k \rangle$$  \hspace{1cm} (5)

where $k$ is the momentum of the observed electron. By perturbatively expanding the expectation value into the interaction Hamiltonian of the incoming electron beam, eq 4, the expression of the UED signal, eq 1 is obtained.

Closed expressions of the UED signal can be obtained by summing over molecular eigenstates and by separating the charge densities into their electronic and nuclear origins. The resulting contributions are represented by the 12 diagrams depicted in Figure 8.

**Wavepacket Simulations.** To model azobenzene photoisomerization, we perform exact nuclear wavepacket simulations according to the time-dependent Schrödinger equation

$$i\hbar \frac{\partial}{\partial t} \psi = \hat{H}\psi = \left[ \hat{T}_q + \hat{V} \right] \psi$$  \hspace{1cm} (6)

in the reduced-dimensional space of two reactive coordinates $q$. In eq 6, $\psi$ is the nuclear wavepacket, and $\hat{T}_q$ and $\hat{V}$ are the kinetic and potential energy operator. As identified in refs 13 and 23, two nuclear coordinates are relevant for the cis $\rightarrow$ trans photoisomerization. The first one is the reactive carbon–nitrogen–nitrogen–carbon (CNNC) torsion that connects the cis and trans structures at $0^\circ$ and $\pm 180^\circ$. The second coordinate is one of the two CNN bending angles between the azo unit and one of the two benzene rings, where the other angle remains fixed at $116^\circ$. This symmetry breaking is necessary to reach the minimum conical intersection seam that is located between CNNC = $80^\circ$ to $110^\circ$ and CNN = $133^\circ$ and $147^\circ$.

Potential energy surfaces to represent $\hat{V}$ in eq 6 were calculated in ref 23 on the multistate Restricted Active Space Self Consistent Field (RASSCF) and the Second-Order Perturbation Theory Restricted Active Space (RASPT2) levels of theory with the MOLCAS8 program and using the ANO-L-VDZP basis set. An active space of 18 electrons in 16 orbitals was employed, including all $\pi$ and $\pi^*$ orbitals and the two nitrogen lone pairs.
Using this, the nuclear grid was discretized with 600 grid points in CNNC and 256 in CNN. After impulsive excitation of the vibrational ground state wave function to $S_1$, the Chebychev propagation scheme was used to numerically evaluate from the state specific $\sigma$-values the structure of the nuclear and electronic scattering terms. The kinetic energy operator in eq 6 is set

$$\hat{T}_i = \frac{-\hbar^2}{2m} \sum_{r=1}^{M} \sum_{i=1}^{M} \frac{\partial}{\partial q_i} \left[ G_{rs} \frac{\partial}{\partial q_r} \right]$$

(7)

with the G-Matrix computed via its inverse elements

$$\left( G^{-1} \right)_{rs} = \sum_{i=1}^{3N} m_i \frac{\partial \sigma_{rs}}{\partial q_i} \frac{\partial \sigma_{rs}}{\partial q_i}$$

(8)

In the $S_1$ state, periodic boundary conditions are employed along the CNNC torsion. A Butterworth filter was used to absorb the nuclear wavepacket at the borders in the CNN direction, a process that acts as a loss channel and that is not further captured by our Hamiltonian. In $S_0$ the filter was also employed at 0° and 360° of torsion. This absorbs the parts of the wavepacket that have reached the product minimum.

**Electronic and Nuclear Densities.** The state and transition densities $\sigma_i(q,R)$ were evaluated in $2^\circ$ increments in CNNC between 0° and 360° torsion and CNN bending between 80° and 180° (a total of 9180 grid points). They were evaluated from the state specific charge density matrices $\rho_i$ according to

$$\sigma_{E,i}(q, R) = \int d\mathbf{r} \ e^{-i\mathbf{qr}} \sum_{rs} \rho_{is}(\mathbf{R}) \phi_s^*(\mathbf{r}, \mathbf{R}) \phi_s(\mathbf{r}, \mathbf{R})$$

(9)

using the basis set of atomic orbitals $\phi_s(r)$. There are a total of 246 $\phi_s(r)$ orbitals for azobenzene in the ANO-L-VDZP basis (14 for each nitrogen and carbon and 5 for each hydrogen). All 96 electrons of azobenzene contribute to the diagonal state densities $\sigma_{ii}$ while the transition density consists of one electron located in the nitrogen lone pairs (see Figure 1b).

The nuclear charge density was calculated as

$$\sigma_{N,i}(q) = \delta_{ij} \int d\mathbf{r} \ e^{-i\mathbf{qr}} \int d\mathbf{R}_i R_i^2 \chi_i(\mathbf{R}) \delta(\mathbf{r} - \mathbf{R}_i)$$

(10)

where $R_i(\mathbf{R})$ is a function that returns the coordinates of the atom $a$ in real space at a given reduced coordinate $\mathbf{R}$, and $\chi_i(\mathbf{R})$ is the nuclear wavepacket of the state $i$ PES.

Our simulations account for symmetric torsion, that is, CNNC angles between + and $-180^\circ$. This corresponds to mirroring the azobenzene along the molecular plane and results in the complex real-space densities displayed Figure 3, as both positive and negative torsion values contribute equally.
